Genetic erosions in plant cell cultures, especially in chromosome number and ploidy level, have now been known for over 25 years. Until the mid -1970s such changes were considered undesirable and therefore discarded because the main emphasis was on clonal propagation and genetic stability of cultures. However, since the publication on somaclonal variation by Larkin and Scowcroft (1981) there has been a renewed interest to utilize these in vitro obtained variations for crop improvement. Studies conducted during the last decade have shown that callus cultures, especially on peridical subculturing over an extended period of time, undergo morphological and genetic changes, i. e. polyploidy, aneuploidy, chromosome breakage, deletions, translocations, gene amplification, inversions, mutations, etc. In addition, there are changes at the molecular and biochemical levels including changes in the DNA, enzymes, proteins, etc. Such changes are now intentionally induced, and useful variants are selected.

For instance in agricultural crops such as potato, tomato, tobacco, maize, rice and sugarcane, plants showing tolerance to a number of diseases, viruses, herbicides and salinity, have been isolated in cell cultures. Likewise induction of male sterility in rice, and wheat showing various levels of fertility and gliadin, have been developed in vitro. These academic exercises open new avenues for plant breeders and pathologists. Another area of tremendous commercial importance in the pharmaceutical industry is the selection of cell lines showing high levels of medicinal and industrial compounds. Already high shikonin containing somaclones in *Lithospermum* are being used commercially.
